The intention to obtain a biodegradable hydrogel enriched with allantoin is to conform a medium of distribution for this natural extract. In this case allantoin was distributed in two layers. One layer to be released immediately into the area of interest and in a second layer for prolonged action. It is known antibacterial and regeneration properties by allantoin, but until today we can only understand antibacterial mechanism, while its role of this extract in the regeneration process still not understood. [1 - 7]

SEM images of pectin hydrogel enriched with allantoin show a homogeneous distribution in both layers, but more important we could verify a porous structure in the allantoin particle not reported before. This kind of structure could contribute the regeneration properties reported by allantoin, because cells and growing factors could penetrate allantoin as used it as a conjunctive tissue like other porous materials for support matrix do it.

A JEOL microscope model JSM-6010PLUS/LA was used for the analysis. Samples were dried and cut 5X5 mm and the images were taken at low vacuum and 5kV. Figure 1 shows a transversal section where a layer rich in allantoin with approximately 291  $\mu\text{m}$  was observed. Figure 2 shows a longitudinal section of this layer with a particle size distribution between 10 to 50  $\mu\text{m}$ . The roughness observed is an ideal characteristic of a material for tissue regeneration propose.

To obtain a closer image of the natural extract we cover the sample with gold. Moreover, in Figure 3 we could find an unexpected porous structure of allantoin. We observed a nano and microporous size distribution. For this reason, we suggest that allantoin structure could allow penetration of grow factors and cells to promote cell adhesion and tissue regeneration for biomedical proposes.
